Clinical characteristics of mandibular fractures in patients over 50 years of age

Клиничка карактеристика прелома доње вилице код пацијената старијих од 50 година

SUMMARY

Introduction/Objective The most commonly used methods of treatment of mandibular fracture are not always successful in patients of older age groups. This is due to decreased regenerative ability, impaired vascularization, osteoporosis, atrophic changes. The corresponding changes are often found in patients over 50 years of age, especially against the background of loss of a large number of teeth.

The objective was to review the clinical characteristics of mandibular fractures in older patients based on a retrospective analysis of medical records.

Methods A group of patients over 50 years of age was selected and analyzed among patients with mandibular fractures who had been treated for 10 years.

Results A total of 642 patients over 50 years with 1003 fracture lines were identified. This represents 8.53% of the total number of patients with mandibular fractures. Comorbidities were diagnosed in 67% of cases. Significant differences in the distribution of the frequency of fracture lines by localization were identified, depending on the presence or absence of occlusal contact. A high incidence rate of open fractures and bone fragment dislocation was observed both in individuals with or without occlusive contact.

Conclusion Patients over 50 years of age are a statistically important group in the general population of patients with mandibular fractures with a number of clinical features. This study is the largest in the literature by the included number of older people with mandibular fractures, including those with edentulous mandible, which ensures the required level of representation, allowing reliable clinical characterization of this contingent of patients.

Keywords: mandibular atrophy; occlusion; edentulous; older patients

САЖЕТАК

Увод/Циљ Најчешће коришћене методе лечења прелома доње вилице нису увек успешне код старијих пацијената. То је због смањења регенеративне способности, поремећаја васкуларизације, остеопорозе, атрофичних промена. Одговарајуће промене су честе код пацијената старијих од 50 година, нарочито у позадини губитка великог броја зуба.

Циљ студије је преглед клиничких карактеристика прелома доње вилице код старијих пацијената на основу ретроспективне анализе медицинске документације.

Метод Међу пацијентима са преломима доње вилице који су били на лијечењу 10 година изабрани су и анализирани од стране групе пацијената старијих од 50 година.

Резултати Студија је откриле 642 пацијента старијих од 50 година са 1003 линије прелома. Ово представља 8,53% укупног броја пацијената са преломима доње вилице. Коморбидитет је дијагностикован у 67% случајева. Идентификоване су поуздане разлике у расподели учесталости линија прелома локализацијом у зависности од присуства или одсуства оклузивног контакта. Висока учесталост отворених прелома и дислокација костних фрагмената примећена је и код особа са оклузивним контактом и без њега.

Закључак Пацијенти старији од 50 година су статистички значајна група у општој популацији пацијената са преломима доње вилице са низом клиничких карактеристика. Ова студија је највећа у литератури о укљученом броју старијих особа са преломима доње вилице, укључујући и безубојску доњу вилицу, која обезбеђује потребан ниво репрезентативности, омогућавајући поуздано клинички карактеризацију овог контингента пацијената.

Кључне речи: атрофија доње вилице; оклузија; адентија; старији пацијенти

INTRODUCTION

At old age, any injury is a serious threat. This is due to the reduced regenerative ability caused by the depletion of the pool of mesenchymal stem cells, impaired vascularization as a

result of systemic atherosclerosis, and osteoporosis resulting from changes in mineral metabolism. The course of a traumatic disease is significantly influenced by comorbidities, which are common in this age group.

Maxillofacial injuries are not an exception, as they frequently lead to disability, including from the social perspective. It is known that mandibular fractures are one of the most frequent type of facial bone injuries, which also holds true for the individuals of older age groups [1, 2]. However, as a result of the loss of teeth, atrophic changes of the alveolar area and body of the mandible, standard treatment methods are not always effective in these patients [3]. According to several authors, the rate of complications associated only with impaired consolidation reaches 25% [4, 5]. In the age population over 50 years old, people with the loss of a large number of teeth and the lack of occlusal relationships are often found. As a result, they develop atrophic changes in the mandible of varying degrees of severity. Accordingly, its damage, in this case, will have a number of clinical features.

The objective of this article is to review the clinical characteristics of mandibular fractures in older patients based on a retrospective analysis of medical records.

METHODS

Medical records of 7,532 patients with mandibular fractures undergoing treatment in the Maxillofacial Surgery Clinic of the N. I. Pirogov Municipal Clinical Hospital No. 1 (the clinical base of the university department) within a period of 10 years were analyzed. A group of patients over 50 years of age was selected. As noted above, this age criterion was chosen based on the fact that mandibular atrophic changes related to the loss of teeth are common enough at this age thus inevitably influencing the clinical course of a traumatic disease.

At admission, all patients provided a written voluntary consent for the statistical processing of their data.

All procedures performed in this study were in accordance with the ethical standards of the institutional research and with the 1964 Helsinki declaration. Permission from the local ethics Committee has been obtained to conduct this research (protocol from 30.05.2019).

The distribution of patients by gender and age, as well as the presence or absence of comorbidities, was analyzed.

To characterize mandibular fractures, the AO/ASIF [6] classification was applied. This is the most convenient classification for the statistical processing of data in large groups in research studies and it also allows to take into consideration the highest possible number of clinical features of practical surgical significance. According to the requirements of this classification, the following categories were evaluated: F (fracture), L (localization), S (soft tissue), O (occlusion). (Table 1)

RESULTS

In the retrospective study of the archival documents, medical records of a total of 642 patients aged over 50 years were identified, which represents 8.53% of the total number of patients with mandibular fractures. The relative share of older patients in different years ranged from 7.0 to 11.3%, i.e. this parameter remained rather stable. Cumulatively, 1,003 fracture lines were diagnosed in these patients.

A total of 90 patients were female, representing 14% of the total number of the studied group, while 552 patients, which constitutes 86%, respectively, were male.

Comorbidities were identified in a total of 67% of patients. Among these, cardiovascular disorders significantly predominated (Table 2). They were also detected in patients with other types of diseases, as a concomitant condition.

Occlusal contact was present in 305 patients, while 337 had no occlusal contact (O₂ category). The number of fracture lines diagnosed was 477 in the first group and 525 in the second group, respectively. Table 3 shows the distribution of unilateral and bilateral fractures in these groups.

In the O category (occlusion), the distribution of fracture frequency in various regions of the mandible was completely different in patients with preserved dentition and patients with loss of occlusal contact. The corresponding data relative to the total number of fractures are presented in table 4. The incidence rate of fracture lines in various regions of the

mandible relative to the total number of patients with present and absent occlusal contacts is presented in Figure 1.

The distribution of the lines of bilateral mandibular fractures in patients over 50 years of age by their localization in both present and absent occlusal contacts is shown in Table 5.

Dislocated bone fragments were observed in 79.1% of patients without occlusal contacts and in 66.3% of patients with occlusal contacts. The frequency distribution of bone fragment displacement by localization of the fracture line is shown in Figure 2.

DISCUSSION

Thus, the incidence rate of mandibular fractures in individuals over 50 years of age is significantly lower than in other age groups (the maximum rate is reported in individuals aged 20 to 29 years: 37.53%), however they still represent a statistically significant population with specific clinical manifestations. Specifically, they include an increasing number of patients with comorbidities, predominantly cardiovascular disorders. This implies the long-term use of various drugs influencing the function of different body systems (for example, anticoagulants), which should be taken into consideration when planning surgery.

The characteristics of the actual fractures fundamentally depend on the presence or absence of occlusal contacts; their loss leads to severe atrophic changes in the mandible. This affects the distribution of fracture lines by localization. In patients with occlusal contacts, the higher incidence rate of fracture lines is observed in the mandibular angle region, similarly to patients of other age groups. In patients with loss of teeth, fracture lines are most prevalent in the lateral portions of the mandibular body, where the most pronounced atrophic changes occur. According to N. Newman [7], the incidence rate of fracture lines in this region is 57%, which is fully consistent with our results.

We noted that in a rather high proportion of cases (9%) in the O₂ category according to the AO/ASIF classification, bilateral symmetrical fracture lines located in the lateral portions of the mandibular body are diagnosed. In the corresponding age group with occlusal contacts, a single such case was reported; moreover, this patient had bilateral free-end edentulous spaces from the first molars, while fracture lines were immediately behind them.

H.G. Luhr et al. [8] proposed a classification of atrophic jaw changes in patients with fractures, based on the vertical size of the bone. The mandibular height in the area of injury of 16 to 20 mm corresponds to class I atrophy, a height of 11 to 15 corresponds to class II, and a height below 10 mm corresponds to class III. H. Mugino et al. [9] also distinguish extremely severe atrophy with a mandibular height lower than 5 mm. Consequently, the recommendations on performing osteosynthesis of the atrophied mandible based on experimental data [10, 11] and clinical observations [9, 12, 13] depend specifically on the assessment of the vertical size of the mandibular body.

However, atrophy of the body of an edentulous mandible progresses unevenly. The increase in the incidence rate of fracture lines in the L₃ region that we observed in association with the loss of occlusal contacts suggests that atrophic changes in the bone tissue develop predominantly in the lateral portions of the mandibular body, while being less pronounced in the angle and frontal regions. These changes are related precisely with the atrophy of the mandibular body in cross-section, rather than with the loss of its height [14]. These fractures should be characterized as extremely unfavorable because as a result of the abovementioned processes, the contact surface between bone splinters is reduced, which negatively influences bone wound healing and can lead to impaired consolidation. According to Bruce R.A., Ellis E.[5], in 20% of cases healing in this region occurs by syndesmosis, without callus formation. Consequently, it seems reasonable to perform computed tomography scanning when planning treatment if the fracture line is located in the lateral portions of the atrophied mandibular body.

Another factor considerably complicating bone wound healing in cases of severely atrophied mandibular body is luminal narrowing of the inferior alveolar artery; thus, bone tissue blood supply is provided predominantly by periosteal vessels [15], which are severely damaged following injury or surgery.

B. Spiessl [16] described a non-union type of fracture typical for atrophied edentulous mandibles, which in literature is referred to as “elephant’s-foot-like” due to hypertrophy of the bone fragment ends. In this study, in the patients admitted to the clinic we observed non-union atrophic fractures accompanied by necrosis in the area of bone wound margins leading to the formation of secondary sequestra and, respectively, marginal bone defects after their removal (Figure 4).

According to N. A. de Amaratugna [14], fractures in the angle of an edentulous mandible are rare. The author observed only three types of distribution of bilateral fractures by their localization with injury in the condylar process region in all cases. However, in our study, fractures in the mandibular angle area had the second highest prevalence in the O₂ category. We observed 13 different variants of fracture line localization in bilateral fractures. These differences could be related to the higher number of observations included in this study (337 versus 67).

Moreover, fractures in the condylar process region were slightly less frequent than in patients with occlusal contacts. Obviously, changes in the anthropometric parameters in the area of condylar processes in cases of mandibular atrophy do not essentially influence their resistance to injury.

In the current study, we determined that the incidence rate of fractures in the frontal portion of the edentulous mandible is 1.5 times lower than in dentulous subjects.

The structure of etiological factors of mandibular fractures differs by country and even region, however, the fact that in the absence of occlusal contacts fractures commonly occurred following an insignificant impact confirms the view of H. D. Barber [17] of decreased resistance of atrophied mandibles to damaging impact. Nevertheless, the frequency of bilateral fractures was only slightly higher compared to the group of patients with occlusal contacts. No significant differences were found between the two groups by the F category.

There is a widespread opinion expressed long ago by Rowe N.L., Killey H.C. [18] that in older patients the risk of mandibular fracture infections is low, since in edentulous mandibles the injury leads to the detachment of mucosa and periosteum, whereas the fractures remain closed. On the contrary, our data showed that open fractures were diagnosed rather frequently not only in patients with occlusal contacts, but in edentulous patients as well (Table 2). This could be related to the decreased thickness of the mucosa covering the alveolar region of the mandible, which is observed in older patients [19]. Thus, the fracture area communicates with the oral cavity, which can lead to its infection.

The high frequency of bone fragment dislocation observed in the patients included in this study correlates with data reported by other authors [5, 7]. Obviously, the loss of teeth is a significant risk factor contributing to the displacement of splinters.

No unified clear algorithm for managing older patients with mandibular fractures has been developed yet. In practice, considering the presence of comorbidities and atrophic changes in the injured area, there is a tendency to extend the indications for conservative treatment. However, the results of this study show that such an approach is not justified, considering the high incidence rate of open fractures and bone fragment dislocation, which will negatively influence the probability of complications and the subsequent quality of life of older subjects. By contrast, stable fixation of bone fragments contributes to the immediate recovery of the normal mandibular function [20]. Nonetheless, the application of bone plates and screws causes an additional and rather significant injury, which is associated with the risk of subsequent impairment of blood supply to the mandible, including in the area of injury itself [21]. In older patients, a shorter duration of surgery should be attempted; however, the correct plate placement requires a considerable amount of time due to atrophic changes in the mandible [20]. In this regard, preoperative computer planning technologies are currently being developed [22]

To solve this issue, opposite surgical concepts are sometimes proposed. Some authors postulate the principle that “The smaller the bone, the larger must be the plate” [13, 23], while others insist on a minimally invasive approach [9, 24]. It was experimentally shown that although the bone mass is decreased, the minimal acceptable thickness of the bone plate for an atrophied mandible should be at least 2.0 mm [25], since without occlusal contacts the distribution of load and the force generated by the multidirectional action of the masticatory muscles are transmitted directly to the injured area [13, 21]. Whether the use of a bone transplant or tricalcium phosphate with rhBMP-2, fixed by an encircling suture or a locking plate [7, 13, 22, 26, 27], is appropriate or whether the plate should be placed over the periosteum, over the mucosa or directly on the bone [13, 21, 23, 28] remains controversial. Overall, as shown by the results of the most complete Cochrane Review [29], there is no consensus on this issue, which could be explained by the fact that most studies included comparatively small numbers of observations due to the relatively low incidence of such cases in the clinical practice.

To date, there are no reliable randomized clinical trials based on sufficient statistically material that allows to substantiate the advantages of a particular method of treatment of older patients with mandibular fractures at the evidence level, which requires the continuation of the relevant multicenter clinical studies [30].

CONCLUSION

Patients over 50 years of age represent a rather consistent and statistically important subset of the general population of individuals with mandibular fractures. At the same time, a number of clinical features determined by a background of comorbidities and atrophic mandibular changes distinguish them from other age groups.

This study is the largest in the literature by the included number of people over 50 years of age with mandibular fractures, including those with edentulous mandible, which ensures the required level of representation, allowing reliable clinical characterization of this contingent of patients. The presented material could be used for the development of a complex treatment algorithm for elderly patients with mandibular fractures, which would take into consideration both general and local status. This task can be accomplished with a wide approach to the problem overall rather than by separating different clinical aspects.

Table 4. The distribution of mandibular fracture lines by localization in patients over 50 years of age

Dentulous* (n = 477, 100%)						
Injury region	S₀		S₁		S₃	
	n	%	n	%	n	%
L ₁	5	1.0	46	9.7		
L ₂	4	0.8	20	4.2		
L ₃	26	5.5	75	15.8	2	0.4
L ₄	74	15.5	110	23.1	2	0.4
L ₅	11	2.3				
L ₆	102	21.4				
Total	222	46.5	251	52.6	4	0.8
Edentulous (n = 525, 100%)						
Injury region	S₀		S₁		S₃	
	n	%	n	%	n	%
L ₁	12	2.3	14	2.7		
L ₂	14	2.7	15	2.9	1	0.2
L ₃	89	16.9	101	19.2	2	0.4
L ₄	84	16.0	97	18.4	2	0.4
L ₅	14	2.7				
L ₆	80	15.2				
Total	293	55.8	227	43.2	5	1.0

*Category L₈ cases (three cases) are not included in this table

Table 5. The distribution of bilateral mandibular fracture lines in older patients by their localization

Fracture line localization pattern	Dentulous		Edentulous	
	n	%	n	%
L ₁ /L ₃	-	-	2	1
L ₁ /L ₄	14	8.9	5	2.4
L ₁ /L ₅	2	1.2	-	-
L ₁ /L ₆	14	8.9	18	9
L ₂ /L ₄	7	4.4	10	5
L ₂ /L ₅	2	1.3	-	-
L ₂ /L ₆	5	3.2	10	5
L ₃ /L ₃	1	0.6	18	9
L ₃ /L ₄	48	30.4	60	29.9
L ₃ /L ₅	7	4.4	5	2.4
L ₃ /L ₆	23	14.6	32	16
L ₄ /L ₄	21	13.2	21	10.4
L ₄ /L ₆	12	7.7	16	8
L ₅ /L ₅	-	-	2	1
L ₆ /L ₆	2	1.3	2	1
Total	158	100	201	100

Figure 1. The frequency of mandibular fractures among the patients over 50 years of age (number of fracture lines to number of patients ratio)

Paper accepted

Figure 2. The frequency of dislocation of bone fragments in fractures of the mandible among the patients over 50 years of age

Figure 3. Pseudarthrosis of the atrophic type in the angle of the mandible
